Abstract. Since its first detection, the interesting properties of the $T_{cc}(3875)^+$ have made it to be one of the most prominent tetraquark-like states up to date. In this work we present a joint analysis of the T_{cc}^+ and its charge-conjugated partner in a dense nuclear medium. We start by considering both states as purely isoscalar D^*D and $\bar{D}^*\bar{D}S$ -wave bound states, respectively. We use previous results for the in-medium D , \bar{D} , D^* and \bar{D}^* spectral functions to determine the modified two-meson amplitudes. We find important changes in the in-medium mass and width of both tetraquark-like resonances, which become more visible when increasing the nuclear density and molecular probabilities. The experimental confirmation of the found distinctive patterns will support the existence of molecular components in the T_{cc}^+ and $T_{\bar{c}\bar{c}}^-$ wave functions.

1 Introduction

In the past years, the field of hadron spectroscopy has seen a new “golden age” with the discovery of many exotic states which do not fit the conventional quark models. This new revolution, which started with the $X(3872)$ [1], continues to see more new and interesting states to this day. One such state is the doubly-charmed $T_{cc}(3875)^+$ [2, 3], observed in the $D^0D^0\pi^+$ mass distribution with a mass of $m_{\text{thr}} + \delta m_{\text{exp}}$, being $m_{\text{thr}} = 3875.09$ MeV the $D^{*+}D^0$ threshold and $\delta m_{\text{exp}} = -360 \pm 40_{-0}^{+4}$ keV, and a width $\Gamma = 48 \pm 2_{-14}^{+0}$ keV [3]. Among the possible models, the molecular interpretation is being supported due to its closeness to the D^0D^{*+} and D^+D^{*0} thresholds.

More experimental input on this state is thus very welcome in order to determine its internal structure. Recent works have studied the femtoscopic correlation functions of the D^0D^{*+} and D^+D^{*0} channels in heavy-ion collisions (HICs) [4, 5]. Another possible way to gain some insight into the nature of the T_{cc}^+ is to study its behaviour under extreme temperature or density conditions, as has already been performed for the $X(3872)$ [6]. In this work we have followed the previous work of Ref. [6] in order to study the behaviour of the T_{cc}^+ and its charge-conjugated partner the $T_{\bar{c}\bar{c}}^-$ in a dense nuclear environment, with the objective of analysing the finite-density regime of HICs in experiments such as CBM at FAIR.

2 Formalism

In this section, we briefly summarise the formalism of Ref. [7] where this exotic state is generated as a result of D^*D interaction. The T_{cc}^+ state is seen in the $D^0D^0\pi^+$ spectrum, right below the $D^{*+}D^0$ threshold, and has most probably quantum numbers $I(J^P) = 0(1^+)$. Therefore, we start by considering D^*D scattering in vacuum in this channel. We work in the exact isospin limit for the $D^{(*)}$ masses. In this limit, both isospin channels decouple and we are left with a single-channel Bethe-Salpeter equation, which in the on-shell approximation has as solution the unitary T matrix

$$T^{-1}(s) = V^{-1}(s) - \Sigma(s). \quad (1)$$

In the expression above V is a contact potential, and $\Sigma(s)$ is the D^*D loop function. We consider two energy-dependent potential families:

$$V_A(s) = a + bs, \quad V_B(s) = \frac{1}{c + ds}, \quad (2)$$

with a , b , c , and d parameters that can be fixed through Eq. (1) by imposing the mass of the T_{cc}^+ in vacuum to be m_0 and the coupling of the T_{cc}^+ to the D^*D channel to be g_0 :

$$T^{-1}(m_0^2) = 0, \quad \left. \frac{dT^{-1}(s)}{ds} \right|_{s=m_0^2} = \frac{1}{g_0^2}, \quad P_0 = -g_0^2 \Sigma'(m_0^2). \quad (3)$$

We also take into account Weinberg compositeness condition [8] (last equality in Eq. (3)), re-discussed in [9], in order to analyse our results in terms of the molecular probability P_0 instead of the vacuum coupling g_0 . Given that we are working in the exact isospin limit, the physical T_{cc}^+ mass cannot be used, and instead we take $\delta m = -800$ keV with respect to the D^*D threshold [10]. We do not fix g_0 or P_0 to any given value. This allows us to discuss our results in terms of these parameters.

At leading order, the effects of the nuclear medium on the scattering amplitude enter only through the meson loop function in Eq. (1) (the potential is left unchanged):

$$\Sigma(s; \rho) = i \int \frac{d^4q}{(2\pi)^4} \Delta_{D^*}(P - q; \rho) \Delta_D(q; \rho), \quad (4)$$

where the in-medium mesonic propagator can be written as

$$\Delta_U(q; \rho) = \frac{1}{(q^0)^2 - \omega_U^2(\vec{q}^2) - \Pi_U(q^0, \vec{q}; \rho)} = \int_0^\infty d\omega \left(\frac{S_U(\omega, |\vec{q}|; \rho)}{q^0 - \omega + i\varepsilon} - \frac{S_U(\omega, |\vec{q}|; \rho)}{q^0 + \omega - i\varepsilon} \right), \quad (5)$$

being $\Pi_U(q^0, \vec{q}; \rho)$ the meson self energy and $S_U(\omega, |\vec{q}|)$ its spectral function. We use the model developed in Refs. [11–13] for computing the meson self energies. In order to regularise the loop integral of Eq. (4) we use a sharp cutoff over three momentum of $\Lambda = 700$ MeV. Further details on the computation of Eq. (4) can be found in Refs. [6, 7].

The discussion for the $T_{\bar{c}\bar{c}}^-$ runs parallel to that for the T_{cc}^+ , but considering the meson pair $\bar{D}^* \bar{D}$ instead of the D^*D one. The distinction arises from the anti-meson self energies, which divert significantly from those of mesons due to the quite different $\bar{D}^{(*)}N$ and $D^{(*)}N$ interactions [11–13].

3 Results

Here we compare the results obtained in the D^*D and $\bar{D}^* \bar{D}$ channels, where the T_{cc}^+ and $T_{\bar{c}\bar{c}}^-$ poles are respectively found, for densities up to $\rho_0 = 0.17 \text{ fm}^{-3}$ (normal nuclear density).

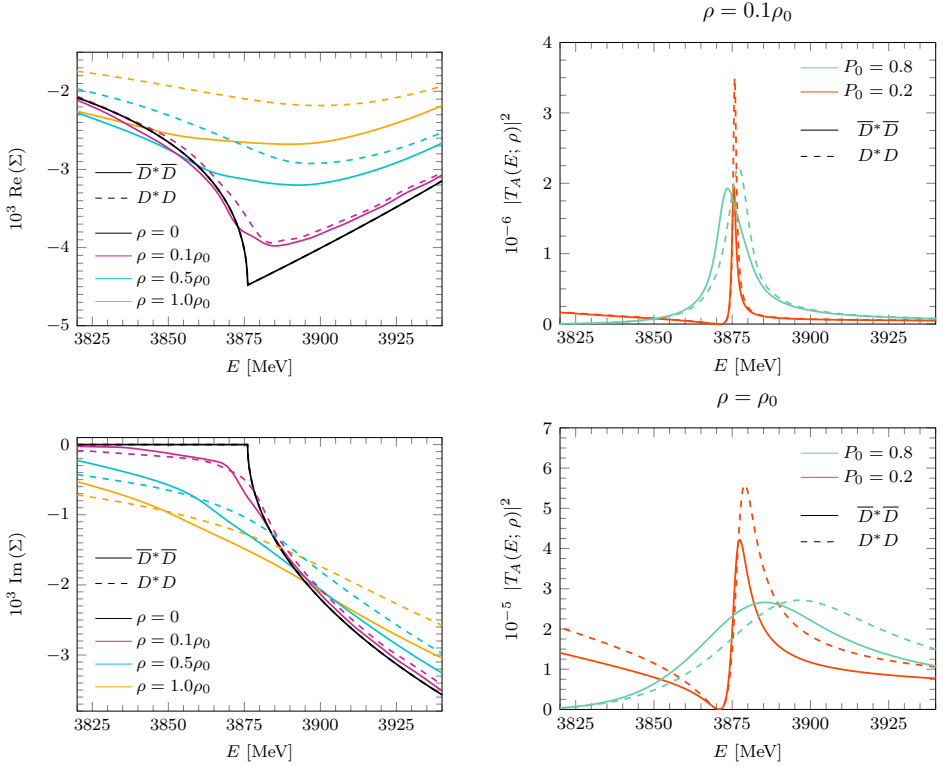

Figure 1. Left column: real (top) and imaginary (bottom) parts of the $\bar{D}^*\bar{D}$ (solid lines) and D^*D (dashed lines) loop functions for different values of the nuclear medium density as a function of the centre-of-mass energy E of the meson pair. Right column: in-medium $\bar{D}^*\bar{D}$ (solid lines) and D^*D (dashed lines) modulus square amplitudes obtained by solving Eq. (1) using the $V_A(s)$ potential, for molecular probabilities $P_0 = 0.2$ (orange) and $P_0 = 0.8$ (blue), and for different nuclear densities.

In the left column of Fig. 1, we plot the real and imaginary parts of the $\bar{D}^*\bar{D}$ and D^*D loop functions. The in-medium loop functions are smooth at threshold, and they develop an imaginary part below threshold. This accounts for the opening of new decay channels for the charmed mesons due to their interaction with the nucleons of the medium. Comparing both loop functions we see that they exactly coincide in vacuum, owing to charge conjugation symmetry, but when increasing density they stray apart. This different behaviour is due to the very different $D^{(*)}N$ and $\bar{D}^{(*)}N$ interactions. Focusing now on the real part of the loop functions we find that it is more negative for $\bar{D}^*\bar{D}$ than for D^*D scattering. This can be naively interpreted as the medium generating more repulsion in the D^*D interaction than in the $\bar{D}^*\bar{D}$ one, but there is no clear answer as the imaginary part is not negligible [6, 7].

On the right column of Fig. 1, we plot the modulus squared of the in-medium $\bar{D}^*\bar{D}$ and D^*D amplitudes for different densities and molecular probabilities, using the V_A potential family presented in Eq. (2). Results using the V_B potential are very similar to those stemming from V_A , especially for high molecular components [6, 7]. We find that the T_{cc}^+ and $T_{\bar{c}\bar{c}}^-$, which were bound states in the vacuum, develop some width when embedded in the nuclear medium. Both states can be easily told apart in the high P_0 scenarios, and become more difficult to differentiate for small ρ and P_0 . Lastly, in the $P_0 = 0.8$ case we can clearly see that the T_{cc}^+ peak sits to the right of the $T_{\bar{c}\bar{c}}^-$ one, pointing to a more repulsive interaction in

the D^*D channel than in the $\bar{D}^*\bar{D}$ one, as we already mentioned when discussing the loop functions.

4 Conclusions

We have studied the behaviour of the $T_{cc}(3875)^+$ and the $T_{\bar{c}\bar{c}}(3875)^-$ in a dense nuclear environment. We have found that the medium effects are sizeable when considering large values of the molecular probability, as opposed to the scenario where the molecular component is small. More specifically, we have observed an important increase in the width of the states and a noticeable shift in their masses. Furthermore, and due to the different $D^{(*)}N$ and $\bar{D}^{(*)}N$ interactions, we have seen that the T_{cc}^+ and the $T_{\bar{c}\bar{c}}^-$ states behave distinctly in the medium, the former shifting towards higher masses than the latter and becoming broader. If the T_{cc}^+ and $T_{\bar{c}\bar{c}}^-$ were to be predominantly compact objects, their density behaviour, although distinct from one another, would likely be very different from the one found in the present work. All in all, we conclude that an interesting way to discern the molecular nature of the tetraquark-like $T_{cc}(3875)^+$ and $T_{\bar{c}\bar{c}}(3875)^-$ is to experimentally determine its density pattern in a dense nuclear environment. This could be tested at experiments such as PANDA (FAIR) with fixed nuclear targets like \bar{p} -nuclei, or in HICs at the CBM (FAIR).
